

Top-quality silage with oxygen-limiting silos

August 18, 2019

Oxygen-limiting silos, unloaded from the bottom, remain popular in Quebec. Their management differs however from that of vertical silos, which are unloaded from the top. A number of factors must be taken into consideration, including dry matter content (DM) at harvest, using dry ice (CO₂) after harvest, and injecting CO₂ at feed-out.

Dry matter content at harvest

Grasses and corn can be ensiled at higher DM contents in oxygen-limiting silos because glass-coated steel silos offer greater compaction and an airtight environment. The table below presents optimal moisture contents and cut lengths for various types of silage.

Table 1. Moisture (%) and theoretical length of cut for different silages
(Adapted from Harvestore)

Silage Type	Moisture (%)	Theoretical length of cut (in.)
Alfalfa	40-45	3/8
Clover	40-45	3/8
Cereal	40-45	3/8

Sudan grass	40-45	3/8
Corn	40-60	3/8 to 1/2
Sorghum	40-55	3/8 to 1/2

Using dry ice after harvest

Unlike conventional tower silos, oxygen-limiting structures are not designed for the harvested silage to be covered in plastic to reduce DM losses when the silo is not completely filled. The solution in this case is to blow dry ice into the silo to create a layer of CO₂ that will prevent the silage from coming into contact with the oxygen in the unfilled part of the silo. This approach is recommended when the silo is filled to less than 80-per-cent capacity. Because CO₂ is heavier than air, the dry ice forms a cloud as it melts, separating the feed from the oxygen. Think of it as a mathematical formula: no oxygen = no yeast = no mold = no moldy crust on the exposed surface of the silage!

The steps are as follows:

1. Order the CO₂ from a gas supplier, such as Praxair (Figure 1), 24 hours before the end of the harvest. Depending on the diameter of the silo, the thickness of the layer of CO₂ should ideally be equivalent to the height of one silo ring (4 ft. 6 in.). Table 2 shows the quantity of dry ice required to fill one silo ring.
2. After adding the last load of silage to the silo, the dry ice is deposited directly from the top. Practically speaking, it is possible to use a blower to introduce the dry ice (Figure 2), but because some will be lost, more dry ice than the quantity recommended above will need to be ordered. Caution! Gloves and safety goggles must always be worn when handling dry ice.

3. It is important to close the silo door after adding the dry ice (see Figure 3).

Table 2. Quantity of dry ice or CO₂ (lbs) required to fill one silo ring for

different silo diameters (Adapted from Harvestore)

Silo diameter (ft.)	Volume of one ring (sq. ft.)	Dry ice or CO ₂ (lbs)
14	705	80
17	1015	115
20	1380	157
25	2280	259
31 (high moisture corn only)	3438	390

At feed-out

Oxygen enters the silo each time silage is fed out, and this can lead to a deterioration of the quality of the remaining silage, particularly during the hot summer months. The way to circumvent the problem is to inject CO_2 from gas cylinders.

The steps are as follows:

1. All glass-coated steel oxygen-limiting silos are equipped with a valve through which CO_2 can be injected (see Figure 4) into the hollow created in the silage at the bottom of the silo.

2. When injecting CO₂, it is very important to take into account the pressure variations that occur in the silo. There is no point in trying to inject CO₂ during a sunny day because it is under those conditions that gases expand, which means the breather bags deflate to let these gases escape (Figure 5). The best time to inject CO₂ is at the end of a sunny day when the breather bags are inflated, which leaves room to inject the gas.
3. It is recommended that CO₂ be injected once the silage has begun to heat, so as to replace the oxygen contained in the silo. The gas should be injected gradually during the night, using an injector such as the one shown in Figure 6. A gas cylinder contains 75 pounds of CO₂, which is equivalent to 660 cu. ft. of CO₂ (at standard atmospheric pressure and 21°C). It is recommended that enough CO₂ be injected to fill two silo rings (refer to chart for exact volume).

Points to remember

Every silage storage method has its advantages and disadvantages. The important thing is to use the practices appropriate for the chosen method so as to obtain good quality silage and maximize the investment. It is also essential to follow appropriate farm safety measures to avoid falling or inhaling toxic gases.

For more information on silages, consult Lactanet's [Guide sur l'interprétation des analyses d'ensilages](#)_(in French only).
